I have a question. I noticed in the GradioGUI looking at the usearch 50 candidates produced by nearest neighbor search using that one dolphin example that the "score" field for each candidate was very high (like about 12 or so). Is that the logit score for that candidate, or something else?

It's something else — it's the **embedding similarity score**, not the logit from the linear classifier.

Specifically it's the **dot product** between the query embedding vector and the candidate embedding vector (both are 1536-dimensional Perch V2 vectors). The default `--score-fn dot` computes this inner product, which can be quite large when the vectors have high magnitude — typical values in the 10-20 range are normal for Perch embeddings.

It's analogous to cosine similarity but not normalized, so the absolute values aren't directly interpretable as probabilities or logits. What matters is the **ranking** — higher dot product = more similar to your query clip. The top-50 results are the 50 closest neighbors in embedding space to your dolphin seed clip.

If you wanted normalized scores (0 to 1 range), you could use `--score-fn cos` instead, which divides by the vector magnitudes. The ranking would be similar but the numbers more interpretable.
